In this work we consider the problem faced by astrophysicists where high energy signal neutrinos must be separated from overwhelming background events. We propose a modification to the usual penalized likelihood approach, to take account of the usage of importance sampling techniques in the generation of the simulated training data. Each simulated multivariate data point has two associated weights, which define its contribution to the signal or background count. We wish to find the most powerful decision boundary at a certain significance level to optimally separate signal from background neutrinos. In this modified penalized likelihood method, the estimation of the logit function involves two major optimization steps and the use of KL (Kullback-Leibler) distance criterion for model tuning. We compare this approach with a non-standard SVM (support vector machine) approach. Results on simulated multivariate normal data and simulated neutrino data are presented. For the neutrino data, since the truth is unknown, we show a way to check whether the proposed method is working properly.

1. INTRODUCTION

A neutrino is a particle that has no charge and almost no mass. Neutrinos may be produced in the center of active galaxies or from highly energetic objects like γ-ray bursts or black holes. Physicists are trying to use the giant device called AMANDA (Antarctic Muon and Neutrino Detector Array) buried deep in the Antarctic ice cap to detect certain neutrino signals within comparatively overwhelming background noise [1, 2]. In computer experiments simulating neutrinos passing through AMANDA, distributions of signal and background are generated by an importance sampling procedure which generates events described by multiple feature variables. Each simulated neutrino can represent both signal and background by assignment of an importance sampling weight. The task is to find the most powerful decision boundary at a certain significance level to distinguish signal neutrino from background neutrino. For a detailed description of the problem and data, see [3]. Because of the curse of dimensionality, usual Monte Carlo methods are not practical. We propose a modified penalized log-likelihood approach to solve the usual multivariate problem with this weighted simulated data. Though this study is motivated by the simulated neutrino data, the proposed method can be applied to other multivariate weighted data.

2. MODIFIED PENALIZED LIKELIHOOD ESTIMATION

2.1. Penalized Likelihood Method for Labeled Data

Let \( x \) be a possibly multidimensional vector of event observables derived from a reconstructed event. Let \( h_s(x) \) be the probability density function for signal vectors and \( h_b(x) \) be the probability density function for background vectors, and let \( \pi_s \) and \( \pi_b \) be prior probabilities of a signal and background observation, respectively. Then the posterior probability that \( x \) is a signal vector is \( p(x) = \pi_s h_s(x)/(\pi_s h_s(x) + \pi_b h_b(x)) \). The logit \( f(x) \) is defined as \( \log[p(x)/(1-p(x))] \equiv \theta + \log(h_s(x)/h_b(x)) \), where \( \theta = \log(\pi_s/\pi_b) \). We will estimate the logit \( f(x) \) for a particular (implicit) value of \( \theta \), but since the end result is to obtain level curves of \( f \), the particular value of \( \theta \) is not important for the calculations. A modified form of the penalized likelihood estimate [4–6] will be used.

Let \( y_i \) be a random variable that is 1 (signal) with probability \( p(x_i) \) and 0 (background) with probability \( 1-p(x_i) \). So the observed data are actually class labels. Then the likelihood of a single observation \( y_i \) is: \( L = p(x_i)^y_i (1-p(x_i))^{1-y_i} \). The negative log likelihood of (independent) data \( y_1, \ldots, y_n \) is then, in terms of the logit given by

\[
Q(y,f) = \sum_{i=1}^{n} \left[ \log \left( 1 + e^{f(x_i)} \right) - y_i f(x_i) \right].
\]  

We want to find \( f \equiv \sum c_k B_k \in H_K \) (a reproducing kernel Hilbert space (RKHS) [4, 5, 7]) which minimizes the penalized log-likelihood:

\[
I_\lambda(c) = Q(y,f) + \lambda \| f \|_{H_K}^2,
\]

where \( B_k \)'s are basis functions in \( H_K \) and \( \| \cdot \|_{H_K} \) is the function norm in \( H_K \).

This is essentially the penalized log likelihood estimate of \( f \) proposed in O’Sullivan, Yandell and Raynor [8], and is in common use in some fields. Under rather general conditions, which include a proper choice of \( \lambda \), penalized log likelihood estimates are known to converge to the ‘true’ \( f \) as the sample size becomes large [9]. RKHS are discussed in Aronszajn [7] and their use in statistical model building in Wahba [4] and elsewhere. A wide variety of these spaces is available. An RKHS is characterized by a unique positive definite function \( K(\cdot,\cdot) \), and once \( K \) is chosen, the exact minimizer of \( I_\lambda(c) \) is known.
2.2. Penalized Likelihood Method for Weighted Data

The form of the negative log likelihood in equation (1) applies where simulated training data is distributed as \( h_b(x) \) and \( h_s(x) \) through sampling directly from the generating distributions \( \Phi_b(E) \) and \( \Phi_s(E) \), then processing the events \( E \) through a simulation chain which mimics the tracks seen by the AMANDA detector array and the process which extracts variables \( x \) from the simulated tracks. Here, \( E \) means a vector of generating parameters, e.g., neutrino energy, position and arrival direction. However, the results were expected to have extremely long tails which is the region of interest, so an importance sampling scheme has been developed. \( x \) vectors were generated according to a convenient sampling distribution \( g(E) \), and pushed through the detector geometry and variable (\( x \)) extraction. For each \( x_i \) so obtained, two weights were assigned, \( w_s(x_i) = \Phi_s(\tilde{E}_i)/g(\tilde{E}_i) \) for signal and \( w_b(x_i) = \Phi_b(\tilde{E}_i)/g(\tilde{E}_i) \) for background. \( w_s(x_i) + w_b(x_i) \) plays the role as an estimate of relative frequency of \( x_i \) in signal + background while \( w_s(x_i)/(w_s(x_i) + w_b(x_i)) \) plays the same role for the probability of signal given \( x_i \) and similarly for background. The weights satisfy \( \sum_{i=1}^{n} w_s(x_i) = N_s \) and \( \sum_{i=1}^{n} w_b(x_i) = N_b \), where \( N_s \) and \( N_b \) are the predicted numbers of events from the weighted simulation.

Now, if we had multiple unbiased observations at some \( x_i \) as \( y_{ij}, j = 1, \ldots, m(i) \), the likelihood of these observations is: \( L = p(x_i) \sum_{j=1}^{m(i)} y_{ij} (1 - p(x_i)) \sum_{j=1}^{m(i)} (1 - y_{ij}) \). If the samplings at \( x_i \) are biased, then the exponent sums are weighted by \( w_s(x_i) \) and \( w_b(x_i) \) respectively leading to a modified likelihood

\[
Q(w, f) = \sum_{i=1}^{n} \sum_{y_{i1}=0}^{w_s(x_i)} \left\{ w_{y_{i1}} \log(1 + e^{f(x_i)}) - y_{i1} f(x_i) \right\}, \quad (3)
\]

where \( w_{y_{i1}} = w_s(x_i) \) for \( y_{i1} = 1 \) and \( w_{y_{i1}} = w_b(x_i) \) for \( y_{i1} = 0 \). The incorporation of weighted events is thus simply accounted for by weighting the terms in the logarithmic likelihood sum. Further, we can substitute \( w_s(x_i) \) and \( w_b(x_i) \) to obtain an alternative form of the likelihood

\[
Q(w, f) = \sum_{i=1}^{n} \left\{ w_i(x_i) \log(1 + e^{f(x_i)}) - \tilde{p}(x_i) f(x_i) \right\}, \quad (4)
\]

where \( w_i(x_i) = w_s(x_i) + w_b(x_i) \) and \( \tilde{p}(x_i) = w_s(x_i)/w_i(x_i) \).

Notice that, our extension of the penalized likelihood method to weighted data by defining \( Q(w, f) \) in equation (2) as in equation (4) is a natural generalization of the original formulation since equation (4) will reduce to equation (1) in the case of labeled data, which we consider as a special case of weighted data with \( (w_s = 1, w_b = 0) \) representing ‘1’ class and \( (w_s = 0, w_b = 1) \) representing ‘0’ class.

3. IMPLEMENTATION OF THE MODIFIED PENALIZED LIKELIHOOD METHOD

After getting the modified penalized likelihood formulation, we now can move on to look for a ‘good’ estimate of \( f(x) \) whose level curves can be obtained. In our implementation, we use radial basis functions plus constant and linear terms. So,

\[
f(x) = \beta_0 + \beta^T x + \sum_{k=1}^{N} c_k K_s(x, x_{i_k}), \quad (5)
\]

where \( K_s(\cdot, \cdot) \) is the Gaussian kernel with isotropic variance \( \sigma^2 \), \( N \) is the total number of basis functions and the \( x_{i_k}, k = 1, \ldots, N, \) will be chosen as a subset of the \( x_i, i = 1, \ldots, n, \) as described below. Thus, \( f \) will be specified as long as all coefficients, i.e., \( \beta_0, \beta \) and the \( c_k \)'s are determined (note that \( \beta \) is a vector). By letting \( \lambda \| f \|_{H_k}^2 = \lambda \sum_{k=1}^{N} c_k \| K_s(x_{i_k}, x_i) \| \), we put a penalty only on the \( c_k \)'s leaving constant and linear terms unpenalized.

We used a sequence of data driven procedures to fit the model in the sense that we let the data choose the ‘best’ combination of smoothing parameter \( \lambda \), scale parameter \( \sigma \) and number of basis functions \( N \). For a given weighted multi-dimensional data set, we can first transform each variable to make them of comparable scale. Though these preprocessing procedures are not always necessary, they often improve the performance of our algorithm. Then, the entire data set is randomly divided into three subsets of some preset sizes: a training set, a tuning set and a testing set. After that, we randomly, but according to weights (large-weighted simulated data points have higher chance to be selected), choose a modest sized set of \( N x_{i_k} \)'s which determines basis functions as a subset of the training set. We solve the minimization problem on a coarse 2-D parameter grid of \( \lambda \) (usually on a log scale) and \( \sigma^2 \) using the training set. For each parameter pair (each point on the log \( \lambda - \sigma \) grid), an iterative Newton-Raphson algorithm is used to solve this convex minimization problem [4]. After the algorithm converges, we calculate the Kullback-Leibler (KL) distance between the tuning set and the fitted model. This is essentially just the first term of \( I_k(c) \) for tuning simulated data with \( f \) replaced by \( \tilde{f} \). Then we find the best parameter combination based on the KL distance over
the coarse grid. Starting from there, a direct-searching simplex method [11] is used to search for a locally best parameter combination according to the KL distance criterion [12]. This whole procedure described above is repeated using \(2N\) bases, then \(4N\) bases and so on, until the improvement on the KL distance is smaller than some preset threshold. We use the coefficients corresponding to the then-best combination of parameters to construct our final estimate of the logit function. Next, the testing set is used to check the goodness of fit of this final model. Finally, the level curves of \(p(x)\) are determined and plotted. These level curves are appropriate for use in conjunction with the approaches in [13, 14]. Finally, the real data can be analyzed by applying the thresholds given by the level curves of \(p(x)\), see [2].

4. RESULTS ON SIMULATED MULTIVARIATE NORMAL DATA

Instead of using the neutrino data, for which we don’t know the truth, we first test our algorithm on simulated multivariate data. For plotting convenience we show a two dimensional example. Our algorithm has been tested extensively on higher dimensional simulated data (in particular 5-D, which is the expected dimension of the neutrino data) with success. We generate a random sample of \(x\)’s from a 2-D uniform distribution (which plays the role of \(g\) over a square. We then associate with each \(x_i\) two distinct 2-D Gaussian density values \((w_s(x_i)\) for signal, \(w_b(x_i)\) for background), giving a simulated data set consisting of the \(x_i\)’s and their associated \(w_b\)’s and \(w_s\)’s. The sum of the two 2-D Gaussian distributions is shown in Figure 2(a).

For a particular run with sample size 1000 (among which we randomly pick 400 for training and another 400 for tuning), the result for the level curve corresponding to \(p = 0.9\) is shown in Figure 1. Since we know the truth here, the data points are colored green if the true \(p\) is less than or equal to 0.9 and black otherwise. The red line is the level curve found by our algorithm, which is visually almost identical to the true level curve (see Figure 2(c)). We also implemented a nonstandard support vector machine (SVM) [15] (the parameters are tuned in a similar way to our modified penalized likelihood method) here for comparison. To use a nonstandard SVM to find the level surface corresponding to \(c_y = \left\{ \begin{array}{ll} r & \text{if } y = -1; \\ 1 & \text{if } y = 1, \end{array} \right.\) and \((\tau)^+ = \tau\) if \(\tau > 0\) and 0 otherwise. We minimize this nonstandard SVM criterion while tuning the smoothing parameter and scale parameter through iteratively calling the well-known SVM software \(SVM^t\) (version 4.0), which gives the blue line in Figure 1 as the estimated decision boundary.

\[
1 - \sum_{i=1}^{n} \sum_{y=-1,1} w_{iy} c_y [(1 - yf(x_i))_+] + \lambda \| f \|_{H_b}^2
\]

where

\[
w_{iy} = \left\{ \begin{array}{ll} w_b(x_i) & \text{if } y = -1; \\ w_s(x_i) & \text{if } y = 1, \end{array} \right.
\]

and \((\tau)^+ = \tau\) if \(\tau > 0\) and 0 otherwise. We minimize this nonstandard SVM criterion while tuning the smoothing parameter and scale parameter through iteratively calling the well-known SVM software \(SVM^t\) (version 4.0), which gives the blue line in Figure 1 as the estimated decision boundary.

It is worth mentioning that, our proposed penalized likelihood method estimates the logit function over the domain of the observed \(x\)’s, hence it is able to give all level curves of the logit (and thus \(p\)) simultaneously, while SVM classifiers are targeted at one level curve at a time, i.e. they are meaningful only for the classification boundary. This point may be understood via Figure 1 of [16]. SVM classifiers come into their own when the classes are (nearly) separable, but in our application that is not the case. In Figure 2, we show further results from our 2-D example. The color bar beside plot(b) codes the relative importance \(w_s + w_b\) (in log scale) for each data point, and the estimated \(p\) for the 200 data points in the test set is plotted against the true \(p\). (The 200 points from the test set are particularly dense near 0 and 1.) We can see that the estimated probabilities (obtained from the estimated logit) match the true probability very well except for several points of very small importance that are colored in blue. Furthermore, by comparing the true and estimated level curve plots in (c) and (d), we can conclude that we are estimating the true logit function very well over the domain of the data.
5. RESULTS ON SIMULATED NEUTRINO DATA

5.1. Logit Function Estimation

The simulated neutrino data consists of five variables along with the weights [17]. The variables are based on parameters derived from a maximum likelihood reconstruction of the particle track in the detector. For detailed information on the detector, reconstruction, variables and analysis procedure, see [17]. We had 10,000 simulated neutrino events, and divided them into 40% training, 40% tuning and 20% test sets. The five variables are first rescaled using their own sample weighted standard deviation after a log transformation. Then, we run our algorithm with the transformed data. We transform them back when plotting the results. The estimated logit function enables us to estimate the probability of an event being a signal neutrino at any point (within the domain of the data) in the 5-D observational space. We show a level curve plot of a 2-D cross section of that 5-D space in Figure 3, where other three variables have been fixed at their sample medians.

5.2. Checking the Goodness of the Estimate

Astrophysicists use very complex computer programs to simulate the observations of neutrinos passing through the AMANDA detector. Even though the parameters related to the simulation are known, the probability of an event being a signal neutrino in the 5-D space is only estimated at the data points where the simulation took place. We can’t construct a plot as in Figure 2(b) since we don’t know the truth. We can only check whether the estimates reasonably reflect the simulated information.
FIG. 3: Level curves: \( p = 0.1, 0.5, 0.9, 0.95 \) and 0.99 on a 2-D cross section in the 5-D observational space of the neutrino data. \( N = 500 \) basis functions were used.

We try to evaluate the estimated probability surface using a method in common practice among physicists. We take all the \( x \)'s whose estimated probability of signal falls into one of ten equally spaced bins from 0 to 1. Then for each bin we calculate the ratio of the sum of all the signal weights of the \( x \)'s to the sum of all the signal + background weights of those \( x \)'s. Call this the level-binned observed \( p \). We plot the result for the \( j \)th bin against the midpoint of the bin, i.e., for the bin [0.4, 0.5], we plot the level-binned observed \( p \) against 0.45, and similarly for the other bins. If we estimate the probability reasonably well, based on the simulated, weighted data, we should have these ten points falling close to the 45-degree line, which is what we observe in Figure 4 for our neutrino data. The color coding of the points represents the relative signal + background weights of the \( x \)'s in each bin, on a log scale.

FIG. 4: x-axis: Midpoints of 10 probability bins. y-axis: ratio of the sum of signal weights to the sum of signal + background weights for data points in each bin.

6. CONCLUSIONS

We have developed a feasible and effective computational method to obtain modified penalized likelihood estimates for signal detection probability in the context of five dimensional data as might be extracted from tracks observed by the AMANDA neutrino detector, where the data simulator has employed importance sampling. We showed result obtained by implementing the proposed method on a simulated neutrino data set before describing a way to check the goodness of our estimation. We have also compared the penalized likelihood method to the nonstandard support vector machine, similarly tuned, on a simulated multi-dimensional problems similar to the AMANDA problem, which can be characterized as having a certain amount of overlap between the signal and background distributions. In the examples of that nature, with significant overlap of the signal and background, the penalized likelihood method is competitive to the comparable nonstandard SVM for classification purposes.
